MICROECONOMICS

Chapter 2

How Economists Work

This chapter provides an introduction to the methods that economists use in their research. We integrate an introduction to graphing into our discussion of how economists present economic data and how they test economic theories.

In our experience, students typically do not learn enough about the connection between theory and evidence, and how both are central to understanding economic phenomena. We thus recommend that considerable emphasis be placed on Figure 2.1, illustrating the process of going from model building to generating hypotheses to confronting data and testing hypotheses, and then returning to model building (or rebuilding). There is no real beginning or end to this process, so it is difficult to call economics an entirely “theory-driven” or “data-driven” discipline. Without the theory and models, we don’t know what to look for in the data; but without experiencing the world around us, we can’t build models of human behavior and interaction through markets. The scientific approach in economics, as in the “hard” sciences, involves a close relationship between theory and evidence.

The chapter is divided into five sections. In the first section, we make the important distinction between positive and normative statements and advice. Students must understand this distinction, and that the progress of any scientific discipline relies on researchers’ ability to separate what they believe to be true from what they would like to be true. We conclude this section by explaining why economists are often seen to disagree even though there is a great deal of agreement among them on many specific issues.

The second section explains the elements of economic models and theories. We emphasize how the model’s definitions and assumptions lead, through a process of logical deduction, to a set of conditional predictions.

We next examine the testing of theories. It is here that we focus on the interaction of theory and empirical observation (Figure 2.1). We examine briefly several aspects of statistical analysis, including the difference between refutation and confirmation, and the even more crucial distinction between correlation and causation.

The fourth section of the chapter deals with economic data. We begin by explaining how economists use data to learn how the economy works and to test their theories. We then make the distinction between cross-sectional and time-series data, at which point the student is introduced to two types of graph.

This brings us to the chapter’s final section, on graphing. We show how a relation can be expressed in words, in an equation, or on a graph. We discuss functions and functional forms, and then go into considerable detail on linear functions, slope, non-linear functions, and functions with minima and maxima. In this discussion, the student is introduced to the concept of the *margin*, described as the change in Y in response to a one-unit change in X . In all cases, the graphs apply to real-world situations rather than abstract variables. Pollution abatement, baseball bat production, firm profits, and fuel consumption are our main examples.

■ Answers to Study Exercises

Question 1

- a. In the U.S. wheat sector, the amount of rainfall on the Kansas prairies is an exogenous variable; the amount of wheat produced is an endogenous variable.
- b. To the U.S. market for coffee, the world price of coffee is exogenous; the price of a cup at Starbuck’s is endogenous.
- c. To any individual student, the widespread unavailability of student loans is exogenous; their own attendance at university or college is endogenous.
- d. To any individual driver, the tax on gasoline is exogenous; his or her own decision regarding which vehicle to purchase is endogenous.

Question 2

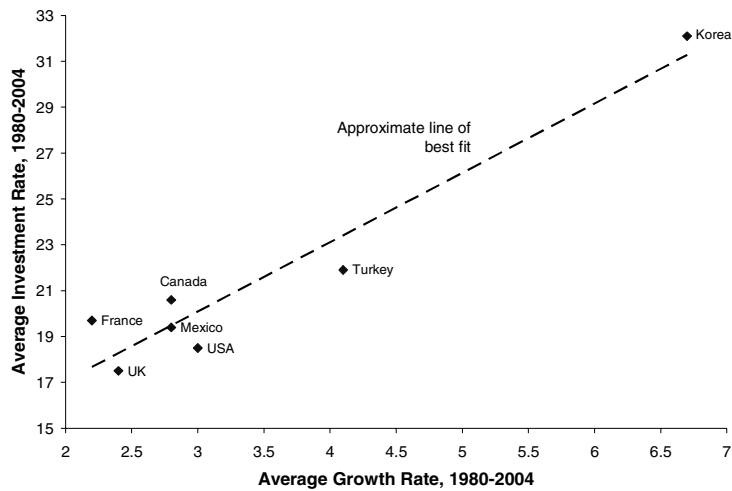

- a. These data are best illustrated with a time-series graph, with the year shown on the horizontal axis and the interest rate shown on the vertical axis.

- b. These cross-sectional data are best illustrated with a bar chart.

These cross-sectional data are best illustrated in a scatter diagram; the “line of best fit” is clearly upward sloping, indicating a positive relationship between average investment rates and average growth rates.

Question 3

- Along Line A, Y falls as X rises; thus the slope of Line A is negative. For Line B, the value of Y rises as X rises; thus the slope of Line B is positive.
- Along Line A, the change in Y is -4 when the change in X is 6. Thus the slope of Line A is $\Delta Y/\Delta X = -4/6 = -2/3$. The equation for Line A is:

$$Y = 4 - (2/3)X$$

- Along Line B, the change in Y is 7 when the change in X is 6. Thus, the slope of Line B is $\Delta Y/\Delta X = 7/6$. The equation for Line B is:

$$Y = 0 + (7/6)X$$

Question 4

Given the tax-revenue function $T = 10 + .25Y$, the plotted curve will have a vertical intercept of 10 and a slope of 0.25. The interpretation is that when Y is zero, tax revenues will be \$10 billion. And for every increase in Y of \$100 billion, tax revenues will rise by \$25 billion. The diagram is as shown below:

Question 5

a. For each relation, plot the values of Y for each value of X . Construct the following table:

(i) $Y = 50 + 2X$		(ii) $Y = 50 + 2X + .05X^2$		(iii) $Y = 50 + 2X - .05X^2$	
X	Y	X	Y	X	Y
0	50	0	50	0	50
10	70	10	75	10	65
20	90	20	110	20	70
30	110	30	155	30	65
40	130	40	210	40	50
50	150	50	275	50	25

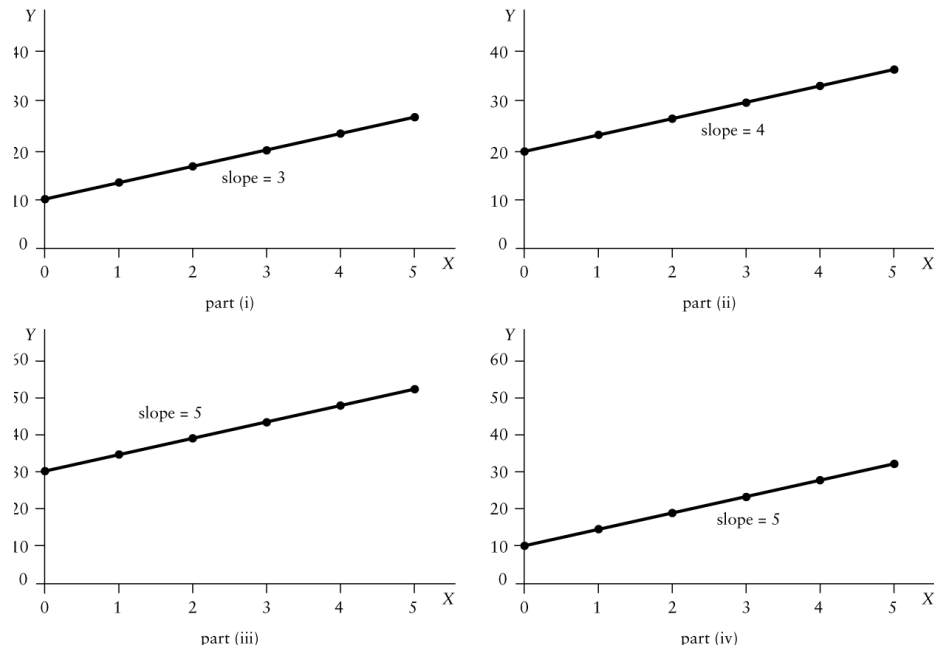

Now plot these values on scale diagrams, as shown below. Notice the different vertical scale on the three different diagrams.

- b. For part (i), the slope is positive and constant and equal to 2. For each 10-unit increase in X , there is an increase in Y of 20 units. For part (ii), the slope is always positive since an increase in X always leads to an increase in Y . But the slope is not constant. As the value of X increases, the slope of the line also increases. For part (iii), the slope is positive at low levels of X . But the function reaches a maximum at $X = 20$, after which the slope becomes negative. Furthermore, when X is greater than 20, the slope of the line becomes more negative (steeper) as the value of X increases.
- c. For part (i), the marginal response of Y to a change in X is constant and equal to 2. This is the slope of the line. In part (ii), the marginal response of Y to a change in X is always positive, but the marginal response increases as the value of X increases. This is why the line gets steeper as X increases. For part (iii), the marginal response of Y to a change in X is positive at low levels of X . But after $X = 20$, the marginal response becomes negative. Hence the slope of the line switches from positive to negative. Note that for values of X further away from $X = 20$, the marginal response of Y to a change in X is larger in absolute value. That is, the curve flattens out as we approach $X = 20$ and becomes steeper as we move away (in either direction) from $X = 20$.

Question 6

The four scale diagrams are shown below, each with different vertical scales.

Question 7

This is a good question to make sure the student understands the importance of using weighted averages rather than simple averages in some situations.

- The simple average of the four regional unemployment rates is equal to $(4 + 5 + 8 + 6)/4 = 5.75$. Is 5.75% the “right” unemployment rate for the country as a whole? The answer is no because this simple, unweighted (or, more correctly, equally weighted) average does not account for the fact that the Northeast and South are much larger in terms of the labor force than either the Midwest or West, and thus should be given more weight than the other two regions.
- To solve this problem, we construct a weighted average unemployment rate. We do so by constructing a weight for each region equal to that region’s share in the total labor force. These weights are:

Northeast:	weight = $55/100 = 0.55$
South:	weight = $25/100 = 0.25$
Midwest:	weight = $5/100 = 0.05$
West:	weight = $15/100 = 0.10$

Using these weights, we now construct the average unemployment rate as the weighted sum of the four regional unemployment rates.

$$\text{National unemployment rate} = (0.55 \times 4) + (0.25 \times 5) + (0.05 \times 8) + (0.15 \times 6) = 4.75$$

This is a better measure of the national unemployment rate because it correctly weights each region’s influence in the national total. Keep in mind, however, that for many situations the relevant unemployment rate for an individual or a firm may be the more local one rather than the national average.

■ Answers to Discussion Questions

Question 1

- a. The issues concern the costs and benefits of applying fiscal or monetary stimulus to an economy (about which students cannot yet say a lot in detail). Some of the normative issues will relate to the reader's evaluation of the current government leaders, such as the president and the chairman of the Federal Reserve. This can be turned into an interesting illustration of how our value judgments can affect our assessment of positive but uncertain issues (in this case the costs and benefits of stimulation).
- b. North Americans are likely to emphasize the economic harm to the rest of the world done by these subsidies; Europeans are likely to stress the social (and political) harm done by eliminating them.
- c. Positive questions relate to the effects of competition on the quality of education. Normative questions may relate to whether it is desirable to have the resulting changes in the quality of education or on the distribution of income.
- d. Positive issues relate to the cost of purchasing insurance and whether medical costs for the uninsured are passed along to people who are insured. Normative issues include how much the government should subsidize the cost of purchasing insurance for the poor. These types of issues were debated when Massachusetts adopted an (almost) universal health insurance system in 2006.

Question 2

Examples of some of the positive arguments are: (1) people who smoke cigarettes are less productive in their jobs; (2) smoking imposes costs on those around the smoker who breathe in the second-hand smoke; and (3) people who smoke have more serious illnesses at the end of their lives, the treatment of which uses resources that could be applied to others.

Examples of some of the normative arguments are: (1) smoking is addictive and we should not permit people to engage in addictive behavior; (2) smoking kills people and we should not allow people to kill themselves; and (2) advertisements of tobacco companies are frequently aimed at children or adolescents, and we must protect this segment of society from risks they cannot properly evaluate.

Question 3

There are, of course, many possible answers to each part. Here we list only one possible answer.

- a. Surveying (over small areas)
- b. Framing an equal-pay-for-equal-work statute
- c. The seventh (final) game of the World Series
- d. This assumption is useful, for example, for examining an individual's saving behavior. In general, any issue in which time is important clearly cannot be examined with a one-period model. Adding only a second period (and ignoring all others) often is all that is necessary to generate valuable insights about behavior over time.
- e. In a world with only one good, it is not possible to discuss substitution between goods. But in a model with many goods, it may be difficult to mentally keep track of all the substitution that is going on. Thus, if one wanted to think about how a tariff on good *X* would affect the production of other goods, the central intuition would be well developed in a two-good model.

- f. This assumption is a convenient simplification for the standard economic theory of utility maximization. As long as self-interest is the most important motive most of the time, then concentrating on it will be an acceptable simplification that will yield predictions that are accurate most of the time.

Question 4

- a. We must first clarify what is meant by “best.” Three of many possible meanings are “the highest income per capita,” “the greatest equality of income,” or “the greatest growth rate.” Each of the resulting statements is testable, and at least one is wrong.
- b. Some students may have strong reactions. They will find it harder to specify their views in empirically testable terms. The statement could be phrased this way: “The higher and more easily obtained are unemployment benefits, the higher will be the rate of unemployment.” (Even if true, this is a long way from destroying the work ethic.) Students who are inclined to believe the view given in the question should be probed about the duration of unemployment insurance benefits.
- c. The following restatement is one: “Robotics—the substitution of automated processes for human labor—will not only eliminate specific jobs, it will permanently decrease employment opportunities of a large group in the population who lack, and cannot acquire, technological skills.” The same kind of assertion has been made about almost every form of technological advance from the time of the steam engine and the cotton gin. This may lead one to be skeptical of the assertion but does not prove it to be wrong since the future may be different from the past in this respect.
- d. Measurable effects might be on wages, unemployment, participation rates, and the structure of jobs filled by women. Once again, the gap between the possibly significant quantitative effects in these dimensions (if they exist) and the vague “better off” needs to be stressed.
- e. One possible restatement is this: “Free trade will increase the income of some people and lower the income of others, but the income gains will outweigh the income losses.” Here, emphasis must be placed on the difference between improving *everybody’s* income and improving *average* income.

Question 5

If there are “believers” and “skeptics” for any of these alleged phenomena, a class can learn from a discussion between the two sides. Emphasis is not on high school debating tactics but trying to get a meeting of minds on what is acceptable evidence that might help to reduce or remove the disagreement.
